ABSTRACT

As part of the first high resolution far-IR spectral survey of the Orion KL region (Lerate et al. 2006), we observed 20 CO emission lines with J_{up}=16 to J_{up}=39 (upper levels from $\approx$ 752 K to 4294 K above the ground state). Observations were taken using the Long Wavelength Spectrometer (LWS) on board the *Infrared Space Observatory (ISO)*, in its high resolution Fabry-Pérot (FP) mode ($\approx$ 33 km s^{-1}). We present here an analysis of the final calibrated CO data, performed with a more sophisticated modelling technique than hitherto, including a detailed analysis of the chemistry, and discuss similarities and differences with previous results. The inclusion of chemical modelling implies that atomic and molecular abundances are time-predicted by the chemistry. This provides one of the main differences with previous studies in which chemical abundances needed to be assumed as initial condition. The chemistry of the region is studied by simulating the conditions of the different known components of the KL region: chemical models for a hot core, a plateau and a ridge are coupled with an accelerated Λ-iteration (ALI) radiative transfer model to predict line fluxes and profiles. We conclude that the CO transitions with 18<J_{up} <25 mainly arise from a hot core of diameter 0.02 pc and a density of 10^7 cm^{-3} rather from the plateau as previous studies had indicated. The rest of the transitions originate from shocked gas in a region of diameter $\approx$ 0.06 pc with densities ranging from 3×10^5–1×10^6 cm^{-3}. The resulting CO fractional abundances are in the range X(CO)=(7.0–4.7)$\times10^{-5}$. A high temperature post-shock region at more than 1000 K is necessary to reach transitions with J_{up} >32, whilst transitions with J_{up} <18 probably originate from the extended warm component. Finally, we discuss the spatial origin of the CO emission compared with that of the next most abundant species detected by the far-IR survey towards Orion KL: H_2O and OH.

1 INTRODUCTION

At a distance of 450 pc, the Orion molecular cloud is the nearest massive star forming region. Molecular emission mainly comes from the Orion Molecular cloud 1 (OMC1) which contains a number of infrared-emitting regions such as the Kleinmann-Low (KL) region (see the review by Genzel & Stutzki, 1989). Since the first spectroscopic measurements in the millimeter, submillimeter and infrared (Storey et al., 1981; Genzel & Stutzki, 1989; Sempere et al., 2000), molecular emission has been shown to arise from several physically distinct regions (Irvine, Goldsmith and Hjalmarson 1987): the hot core, the compact ridge, the ridge, the plateau and the PDR surrounding the quiescent gas (see Figure 1). The hot core and the plateau are characterized by elevated temperature due to star forming activity (the hot core) or as consequence of outflows and shocks (the plateau), while the ridge represents extended, cooler, quiescent material.

The powerful molecular outflow associated with OMC1 was discovered by Zuckerman, Kuiper & Rodriguez-Kuiper

(1976), being later noted as containing a weak bipolarity by Erickson et al. (1982), and subsequently mapped with greater sensitivity and resolution. Recent observations have shown that the observed bipolar high velocity outflow probably originates at the position of radio source I (Menten & Reid, 1995; Gezari, Backman & Werner, 1998; Chandler & Greenhill, 2002). Source I is just 0.5 arcsec from IRc2, which had been believed to be the major source of the luminosity in the region (L≈ $10^5 L\odot$: Genzel & Stutzki, 1989). The hot core is probably a dense clump, or a set of clumps, in the cavity surrounding these locations, with a gas kinetic temperature near 200 K. The main heating mechanism is radiative, warming up the grains and thus inducing thermal evaporation of their icy mantles (Goldsmith et al. 1983).

The Plateau emission comes from a mixture of outflows, shocks and interaction regions where shock chemistry may be dominant, being responsible for the large observed abundance of species such as SO, SO_2 and SiO. These species can be easily formed in the heated gas due to enhancements of the S, Si abundances following grain disruption in the shocked region and OH abundances through gas phase reactions at high temperature. However, fragile molecules such as H_2CO or HDO have been also detected in the plateau, suggesting that small dense condensations may be present in the surrounding outflow (Blake et al. 1986). It is therefore difficult to discriminate between processes due to high-temperature gas-phase reactions or grain surface chemistry.

Interactions between the powerful outflow and quiescent ambient material are thought to give rise to the compact ridge emission, which is also referred to as the southern condensation. This emission region appears to be spatially compact, being revealed in observations of [C I] as a double-peaked structure from a shell of radius ≈ 20 arcsec (Pardo et al., 2005). Finally, there is a surrounding layer of warm photodissociated material, arising from the non-ionising ultraviolet (UV) radiation from the Trapezium OB stars (Rodriguez-Franco et al. 2001).

Among molecular tracers, CO is of particular interest, because of its high abundance and because observations of different transitions can trace regions with significant differences in their physical properties. CO transitions with low J_{up} values trace the less dense gas, with moderate temperatures and constituting the bulk of the outflow, while the highest J_{up} transitions trace either a dense or high temperature gas.

The first Orion-KL far-IR CO line detection was by Watson et al. (1980), with the Kuiper Airborne Observatory (KAO). Their detections of the J=21–20 and J=22–21 transitions, at 124 μm and 119 μm, indicated the presence of at least two different temperature components, with temperatures between 400-2000 K and a density in the range of $1\text{-}5\times10^6$ cm^{-3}. In a more recent analysis of ISO LWS data, Sempere et al. (2000) concluded that the CO emission could be described by three temperature components in the plateau and ridge, with temperatures ranging from 300 to 2000 K and column densities of $N(CO)=10^{17}\text{–}10^{19}$ cm^{-2}. On the other hand, our far-IR survey of Orion-KL (Lerate et al. 2006) showed the presence of P-Cygni line profiles in H_2O and OH transitions, revealing their outflow origin. Recent analyses of these transitions (Goicoechea et al. 2006; Cernicharo et al. 2006) inferred a beam averaged gas temperature of ≈ 100-150 K; however, it is still not clear if these molecules form via high temperature neutral-neutral reactions due to shocks or via desorption from grains. The complexity of the region and the large beam size of the ISO Long Wavelength Spectrometer(≈ 80 arcsec) complicates the spatial differentiation of the molecular emission.

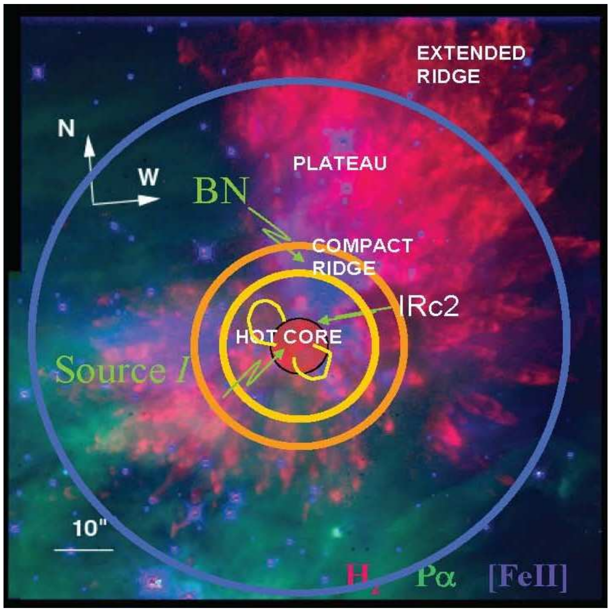

Figure 1. Sketch of the different components in Orion-KL overplotted on the image of Schultz et al. (1999). Colours correspond to the emission in H_2 (red) , P_α (green) and [FeII] (blue). Note that the large circle is the approximate size of the LWS beam.

In this paper we report our analysis of the final ISO LWS-FP CO line detections from our recently published far-IR spectral survey of Orion-KL. Observations of multiple CO lines with the same instrument are of great value, since all the lines have the same instrumental calibration and the same pointing. We used a new approach to modelling the CO emission, in which chemical simulations are carried out independently for each of the main known physical components in the region. The resulting chemical outputs are then coupled with non-local accelerated Λ-iteration (ALI) radiative transfer modelling in order to reproduce the observed line shapes and fluxes.

2 OBSERVATIONS AND DATA REDUCTION

The dataset consists of 26 individual ISO observations in the LWS high resolution modes L03 and L04. The complete list of Target Dedicated Time identification numbers (TDT's) and detailed description of the data processing can be found in Lerate et al. (2006). The angular and spectral resolution achieved across the LWS range was ≈ 80 arcsec and 33 km s^{-1}, although this could vary slightly depending on the LWS detector (Gry et al. 2003). Table 1 summarises the detectors in which the different CO J transitions are observed and the effective aperture for this wavelength in arcsec. The last three columns are the instrumental resolving power, the FWHM of the resolution element and the overall calibration accuracy in μm. (Swinyard et al 1996). The velocity accuracy achieved for the LWS FPs during the mission is quoted as 6 km s^{-1} for FPS and 13 km s^{-1} for FPL (Gry et al 2003). However, it should be noted that this is only for the absolute velocity, i.e. comparing to an absolute standard of rest for an individual object, and arises primarily in the uncertainty in the knowledge of the absolute velocities of the sources used for the calibration of the instrument. For comparison of relative velocities of components within a given source, the better measure to take is the statistical error on the centroid found from repeated measurement of the same line on the same source over the course of the mission (ibid). For both FPs we take this as ± 5 km s^{-1} over all wavelengths.

Observations were centred at either RA J2000 05$^{\rm h}$ 35$^{\rm m}$ 14.12$^{\rm s}$ Dec(2000)– 05° 22′ 22.9″ on at RA(J2000) 05$^{\rm h}$ 35$^{\rm m}$ 14.45$^{\rm s}$ Dec(J2000)– 05° 22′ 30.0″, including both the BN object and IRc2 in the beam.

The data processing was carried out using Offline Processing (OLP), the LWS interactive Analysis (LIA) package version 10 and the ISO Spectral Analysis Package (ISAP). Further processing was also carried out by including dark current optimisation, deglitching and removal of the LWS grating residual profile (Lerate et al. 2006). A full grating spectrum with lower spectral resolution was also acquired but these data suffer from detector saturation effects. Thus only the Fabry-Pérot observations are considered in the present work.

3 THE CHEMICAL AND RADIATIVE TRANSFER MODELS

The three main components in Orion-KL (hot core, plateau and the ridge) were chemically modelled. The model is made from a two stage calculation: in Stage I the chemical evolution from diffuse gas to a dense core is computed. In Stage II the chemical evolution of the plateau and ridge are investigated.

The time-dependent outputs from the chemical model are the fractional abundances of gas-phase and grain surface species. The fractional abundance of CO was then coupled with a radiative transfer model and line profiles and intensities directly compared with observations. The method and the models are similar to those used by by Benedettini et al. (2006) to study the chemical structure of molecular clumps along chemically rich outflows. Each component is modelled independently. The final synthetic line spectrum is obtained by adding up the contribution of the three components.

3.1 The chemical models: the hot core, the plateau and the ridge

The hot core model is described by Viti et al. (2004a). It is a modification of the model described by Viti & Williams (1999), where more detailed information about the molecules included and main reactions can be found. The model follows the chemical evolution of a free-fall collapsing cloud. The chemical evolution of the molecular species is then investigated after typical densities of hot cores (∼ 10^{7} cm^{-3}) have been reached. The effect of an infrared source is simulated by an increase in the gas and dust temperature (see Viti et al. 2004a for more details). The initial and final densities of the collapsing core are 4×10^{2} cm^{-3} and 10^{7} cm^{-3}. The diameter of the core is 10 ″ (≈ 0.02 pc), as estimated by observations of hot cores (e.g. Blake, Sutton and Masson, 1986) and the final visual extinction is ≈ 400 mag. During collapse, gas-phase species accrete, or freeze-out, onto the dust. The efficiency of accretion, f$_{r}$, is a free parameter and a grid of conditions for different f$_{r}$ values was investigated, from f$_{r}$=0.03–0.63 (f$_{r}$=1 means 100% efficiency). The best fit model was for f$_{r}$=0.23, which led to 98% of the CO in the form of ice at the end of Stage I.

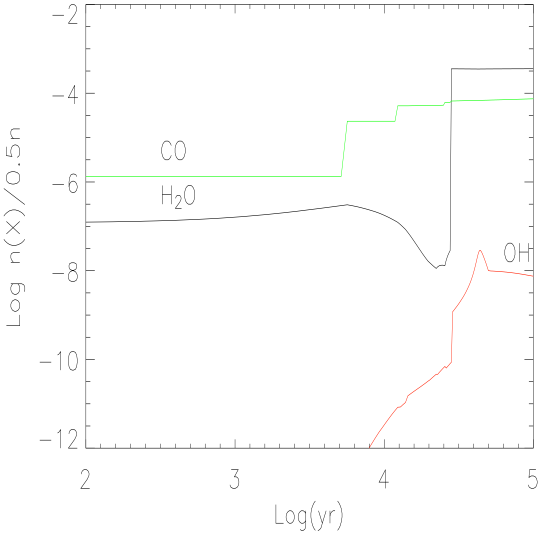

Figure 2. Time evolution of the abundances of CO, OH and H_2O in the Hot Core model.

The models used to simulate the plateau and ridge are described by Viti et al. (2004b). As in the hot core model, we have a two phase calculation, where the gravitational collapse occurs in Stage I. Both the ridge and the plateau components are believed to be affected by shocks due to the outflows activities. In Stage II we therefore simulate the presence of non-dissociative shocks by an increase in temperature at an age of ≈ 1000 yr, corresponding to the dynamical timescale of the main outflow observed in the KL region (Cernicharo et al. 2006). The efficiency of freeze-out during Stage I, the shock temperatures, and the unshocked gas temperatures are free parameters and Table 2 lists the choice of these parameters for the grid investigated. The parameters were chosen based on the results of previous studies of the Orion-KL components (Blake et al. 1987, Genzel and Stutzki 1989).

3.2 The radiative transfer model

The chemical model produces abundances that are used as inputs to the radiative transfer model SMMOL (Rawlings

J range	FP	Detector	Effective aperture (arcsecs)	Resolving power	Resolution element (μm)	RMS accuracy

& Yates, 2001; van Zadelhoff et al, 2002), along with values for the scale, density, dust temperature and interstellar radiation field. The SMMOL code has accelerated Λ-iteration (ALI) that solves the radiative transfer problem in multi-level non-local conditions. It starts by calculating the level population assuming LTE and the interstellar radiation field as input continuum and then recalculates the total radiation field and repeats the process until convergence is achieved. The resulting emergent intensity distribution is then transformed to the LWS units of flux (W cm^{-2} μm^{-1}) taking into account the different beam sizes (slightly different for each detector) and convolved with an instrumental line profile corresponding to a 33 km s^{-1} FWHM Lorentzian (Polehampton et al. 2007), in order to directly compare with the observations. The main input parameters include molecular data such as molecular mass, energy levels, radiative and collisional rates and also the dust size distribution and opacity. The CO molecular data were taken from molecular public databases (Müller et al., 2001; Schöier et al., 2005). The input parameters also include the gas and dust temperatures of the object to model, such as the kinetic and dust thermal temperature.

We estimated the dust temperature from the LWS grating observation of Orion-KL (Lerate et al. 2006), fitting a black body function of 80 K. The gas kinetic temperature is based on the chemical model input, which varies for the different models considered (Hot Core, Plateau, PDR, see also Table 2). In order to reproduce the observed continuum flux level, we adopted a radiation field equivalent to 10^4 Habings. This value is in agreement with previous continuum studies performed in the submillimeter which constrains the ISRF enhancement to 10^3 to 10^4 times the standard IRSF (Jorgensen et al. 2006). The microturbulent velocity was set to 5 km s^{-1} and different expansion velocities from 15–40 km s^{-1} were also considered for the shocked gas in the Plateau models. The resulting model continuum is plotted in Figure 5 along with the observed CO lines. We estimated an error of less than 30% for the fit to the continuum, being the percentage deviation below the observed continuum for wavelengths up to 120 μm and above the observed continuum for the longest wavelengths.

4 RESULTS

Figures 2, 3 and 4 show the chemical models that best fit our observations. The selection of species to be considered was based on the most abundant molecules detected in our far-IR survey towards Orion-KL (i.e., CO, H_2O and OH). We used a χ^2 fit to compare model line profiles with observations. The modelled lines were rebinned to the same spectral sampling as the observations before the χ^2 fitting. Figure 6 shows the best-fit models compared to the observed CO lines. Table 3 shows the computed densities, temperatures and fractional abundances obtained for the different components. The contributions to the line fluxes and profiles from the different models described below were summed to give the total fluxes listed in Table 3 and the profiles shown in Figure 6. Line peaks are also listed on column four. Quoted error are based on goodness of fit estimation

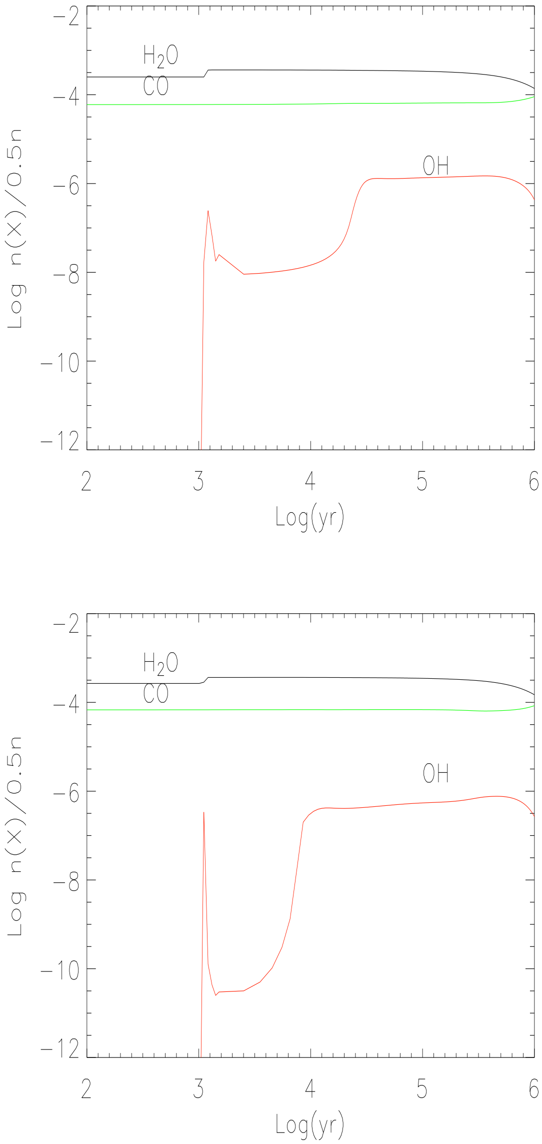

Figure 3. Plateau chemical models PL3 and PL14 (see Table 2) found to provide the best fit to the CO lines (see also Figure 6).

and do not include calibration errors. The overall velocity error should include the calibration error of ± 5 km s^{-1} discussed in section 2. The main results are listed on Table 4 and can be summarized as follows:

- CO transitions with J_{up} <18 (i.e lines at wavelengths > 144.78 μm and upper energy levels E_{up} lower than ≈ 945 K) are best reproduced by a Plateau chemical model (PL2 in Table 1) with a density of 3×10^5 cm^{-3}, reaching a maximum temperature of 300 K. This could correspond to Plateau winds within the extended warm components. Ridge models with lower temperature and densities fail to reproduce these transitions.
- CO transitions with 18<J_{up} <25 (i.e. lines at wavelengths between 104.45 μm and 144.78 μm and with upper level energies between ≈ 1795 K and 945 K) are best reproduced by a Hot Core model with a mass of ≈ 25 M⊙, a density of 1× 10^7 cm^{-3} and a diameter of ≈ 0.020 pc.
- Transitions with 30>J_{up} >25 (i.e lines between 87.19 and 104.45 μm, with upper level energies in the range 2567–1795 K) are best reproduced by a Plateau model (PL3) with a density of 3×10^5 cm^{-3}, simulating a shock that heats the gas to 500 K during a period of 100 yr at the age of 1000 yr.
- Higher energy CO transitions, with J_{up} >30, are best fitted by a Plateau model (PL14) with a higher density, 1×10^6 cm^{-3} and a freeze-out efficiency of 80%, simulating a post-shock region at 1000 K which heats the gas, at an age

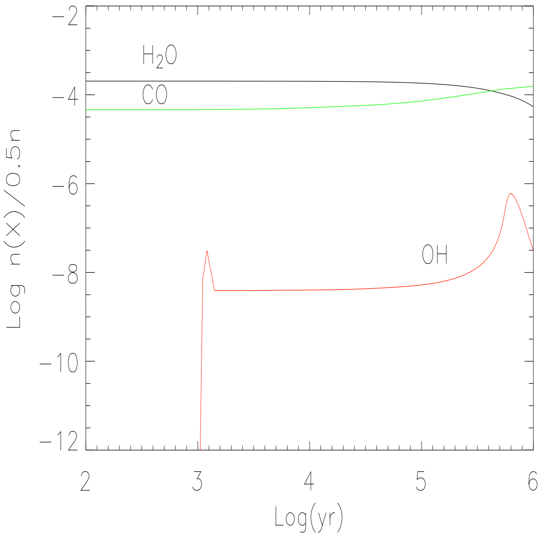

Figure 4. Model PL1, found to fit CO transitions with J_{up} <18 (see also Figure 6).

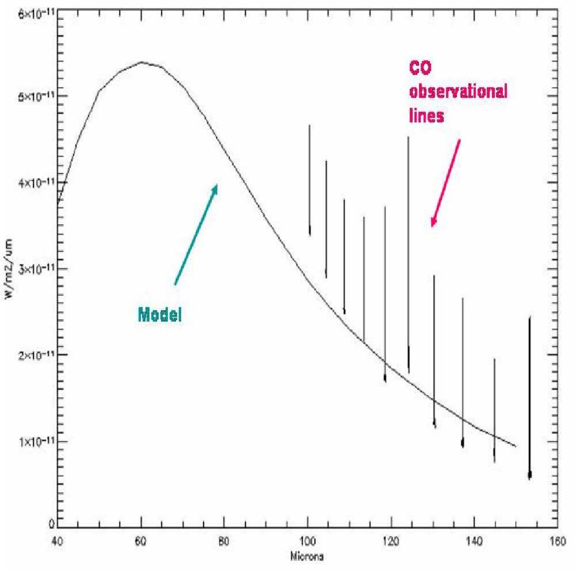

Figure 5. Model of the continuum adopted in the radiative transfer model.

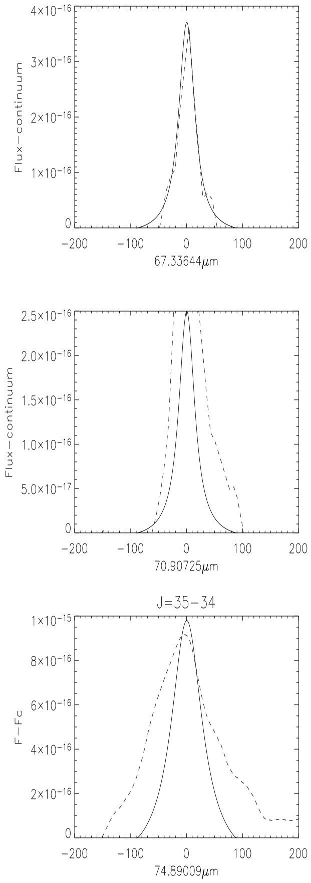

Figure 6. Line profiles from the radiative transfer models (solid lines) over-plotted on the observed CO lines (dotted lines). The ordinate corresponds to the continuum-subtracted flux and the abscissa is the velocity in km s^{-1}. CO transitions with 18<J$_{up}$ <25 (i.e from wavelengths 104.45 to 144.78 μm) are reproduced by the Hot Core model. Transitions with 30>J$_{up}$ >25 (i.e lines between 87.19 and 104.45 μm) are reproduced by the Plateau model PL3. CO transitions with J$_{up}$ >32 are reproduced by the Plateau model PL14 and transitions with J$_{up}$ <18 by model PL1 (see text for a description of these models)

of 1000 yr. All Plateau models had a diameter of ≈ 0.061 pc.

X(CO), the CO/H$_2$ fractional abundance, varies slightly as a function of cloud depth, from 7.0×10^{-5} to 4.7×10^{-5}, with an enhancement in the hot core component. This is an effect of the different densities, and therefore freeze-out efficiencies.

5 DISCUSSION

5.1 The Extended warm component

Our model results indicate that the lowest energy far-IR CO transitions originate from warm (≈ 300 K) and dense (≈ 10^5 cm^{-3}) gas. The derived temperature and density agree reasonably well with those from the combined flux ratios of [O I] 63.2/145.5 μm and [O I] 63.2/[C II] 157.7 μm which yielded a temperature of 300 K and a density of ≈ 10^5 cm^{-3} (Lerate et al. 2006).

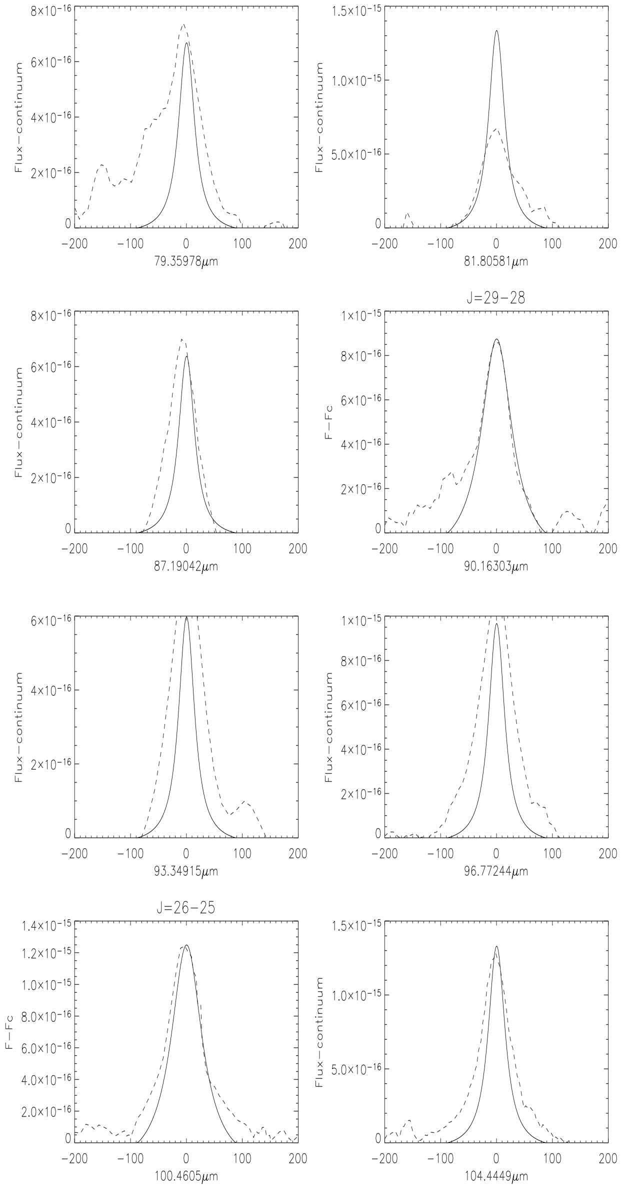

Figure 6. Continued

The results agree with the gas density component described in Sempere et al. (2000) as the extended ridge emission with density of ≈ 10^5 cm^{-3} and temperatures > 120 K. Similar results were found by Maret et al. (2001), however they explained the emission as due to the non-ionising ultraviolet (UV) radiation from the Trapezium stars, i. e., the photodissociation region (PDR).

5.2 The Plateau

The CO transitions with 18<J$_{up}$ <30 can be fitted by a two-component emission region. The low-velocity plateau is modelled by simulating a non dissociative C-type shock of ≈ 30 km s^{-1} which leads to an increase in gas temperature

Table 3. CO line fluxes and summary of the main model parameters and results.

Component	Size (″)	Density (cm^{-3})	T$_{gas}$ (K)	T$_{shock}$ (K)	mco (%)	CO J range
Extended warm gas	30	3×10^5	90	300	60	<18
Hot Core	10	1×10^7	200		98	18–25
Plateau	30	3×10^5	90	500	60	25–30
Plateau	30	1×10^6	100	1000	80	>30

Table 4. Summary of the main components and their physical parameters of size, density, gas temperature, dust temperature and percentage of mantle CO from the CO line modelling.

to 1000 K in a period of ≈ 100 yr, reaching its maximum temperature at an age of 1000 years, followed by fast cooling to temperatures of 100K (as described by Bergin et al. 1998). The density and diameter of this region are 10^6 cm $^{-3}$ and ≈ 0.061 pc respectively, and this model component gives a good fit to the observed high-J CO transitions. Both Sempere et al. (2000) and Maret et al. (2001) agree on the presence of hot and dense gas arising from the shocked region at the interaction of the outflows with the ambient gas. However, their quoted temperatures (1500-2000K) and densities (up to 3×10^7 cm^{-3}) are higher than implied by our models.

The CO transitions with 30>J$_{up}$ >25 are best fitted by a lower temperature shock model. Here the maximum temperature is 500 K, with subsequent cooling down to 90 K. This result provides a new finding, being the first time that these transitions are associated with a low temperature shock. Our interpretation is that this emitting region may be the external plateau, characterized by a density of 3×10^5 cm^{-3}, probably formed as consequence of the interaction of the many condensations in the flow (at lower velocity than in the inner part of the plateau) with the surrounding quiescent medium. Note however that Sempere et al (2000) found that transitions with 18<J$_{up}$ <33 were best reproduced by a higher density component at 10^7 cm $^{-3}$ and T = 400 K. A similar result is presented by Maret et al. (2001) which also includes transitions from J$_{up}$=20–30. We found that in those intervals only transitions with J$_{up}$ >25 are emitted by the plateau, as the remainder are better reproduced by the hot core model, consistent with the high density required by their models.

5.3 The Hot Core

The Orion hot core is well known to be warm (T ≈ 200 K), compact (angular size ≈ 10 arcsec) and dense (10^7 cm^{-3}) (Blake et al. 1986, Wright et al. 1992). Such a hot core can reproduce well the CO fluxes and line profiles with J$_{up}$=18–25. As mentioned in the plateau discussion, previous analyses of these transitions (Sempere et al. 2000; Maret et al. 2001) explain them as coming from the plateau where a high density and temperature ≈ 350–400 K component is needed to reproduce the lines. We find that this high density component is in fact the hot core, where the temperature is close to 200 K. Plateau models of the same density and temperature fail to reproduce these

transitions.

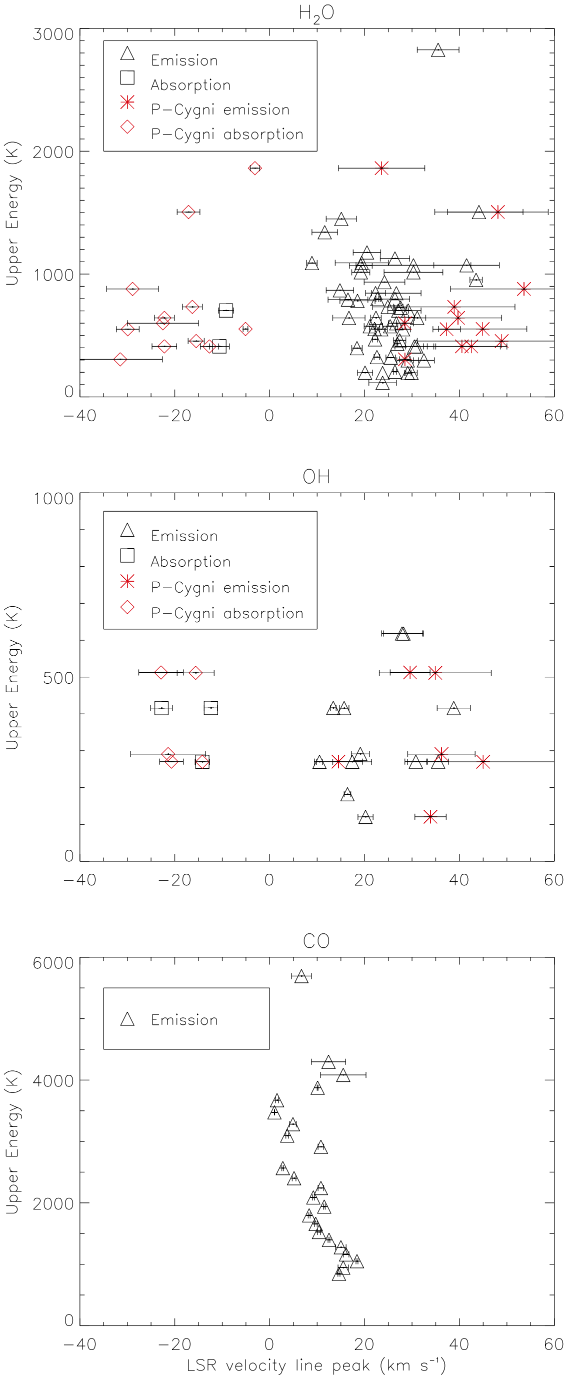

Figure 7. LSR peak velocities of H_2O, OH and CO lines observed towards Orion-KL with the *ISO* LWS-FPs (Lerate et al. 2006). Note that only statistical errors are plotted and do not include the overall calibration uncertainty of ± 5 km s^{-1}

.

5.4 Velocity structure and the far-IR H_2O and OH lines

An analysis of the observed line radial velocities and their FWHMs can be used to distinguish emission originating from different components. However, the lack of spatial resolution complicates the analysis as the dynamical properties are diluted by the large LWS beam. The CO lines mainly peak in the LSR velocity range between +5–15 km s^{-1} (see Figure 7); but, because the line centre uncertainty is ≈ ± 5 km s^{-1} it is difficult to establish whether lines originate from the plateau or from the hot core component. Nevertheless, it seems clear that CO has a different spatial origin when compared to H_2O and OH molecules which have emission lines peaking in the range +20–40 km s^{-1} LSR and lines with pure absorption profiles, which peak at –(10–20) km s^{-1}. Both the OH and H_2O emission have been modelled (Goicoechea et al. 2006, Cernicharo et al. 2006) and it was inferred that they mainly arise from an extended flow of expanding gas at a velocity of ≈ 25 km s^{-1} with a density of $\approx 5 \times 10^5$ cm^{-3} and gas kinetic temperature of ≈ 100 K. The inferred beam-averaged abundances are $X(\mathrm{H_2O})=(2\text{–}3)\times10^{-5}$ and $X(\mathrm{OH})=(0.5\text{–}1)\times10^{-6}$ (Cernicharo et al. 2006, Goicoechea et al. 2006). These physical conditions are close to those found by our model of the plateau; however, we find that the water and OH abundances predicted by our chemical models are respectively higher and lower than those derived by Cernicharo et al and by Goicoechea et al. from radiative transfer model of the observed lines (see Figure 3).

For our models, the higher water abundance is due to (i) high efficiency in the hydrogenation of oxygen on the grains in Stage I, followed by evaporation of the icy mantles in Stage II; and (ii) high temperature reactions occurring during the shock phase (Elitzur and Watson 1978). The latter consist of:

$$O + H_2 \rightarrow OH + H \quad (1)$$

$$OH + H_2 \rightarrow H_2O + H \quad (2)$$

At higher temperatures, OH is also formed via molecular oxygen destruction:

$$O_2 + H_2 \rightarrow OH + OH \quad (3)$$

The high temperatures produced by the shock are necessary to explain the OH abundance of $X(\mathrm{OH})=(0.5\text{–}1)\times10^{-6}$. A shock temperature of at least 1000 K is required to reproduce the OH abundance. Possible explanations for the differences between the physical conditions inferred for the CO-emitting regions and those inferred for the H_2O- and OH-emitting regions include:

- The latter two molecules arise from another physically distinct component, with no contribution from the hot core or the inner plateau.
- The inferred H_2O and OH molecular abundances are in fact very diluted by the large LWS beam, where the contribution from shocked regions is not resolved. In this case, the use of a radiative transfer model alone is not enough to distinguish between the different components, and the resulting abundances may be locally underestimated.

6 CONCLUSIONS

We have analysed the final calibrated high resolution ISO LWS-FP observations of CO lines using chemical models coupled with a non-local Accelerated Lambda Iteration (ALI) radiative transfer model. The main physical parameters of the different components (density, temperature, scale, interstellar radiation field, dust temperature) are introduced in the chemical models together with physical parameters based on literature values for the hot core, plateau, ridge and the PDR surrounding the KL region. This technique allows a better approach to the difficult task of distinguishing between the emission from the different components included in the large ISO-LWS beam. Our modelling results show that CO transitions with $18 < J_{up} < 25$ are reproduced by a hot core model of density $\approx 10^7$ cm^{-3} and a temperature of 200 K. This result suppose a new interpretation of the CO lines origin, as these transitions have been previously interpretated as originated in the Plateau component. Transitions between $25 < J_{up} < 39$ are reproduced by plateau models with densities ranging between 3×10^5–1×10^6 cm^{-3} simulating shocked material at 500–1000 K. Derived CO abundances are summarised in Table 3.

Our chemical models do not agree with the abundances previously found from the far-IR H_2O and OH emission lines (Cernicharo et al., 2006; Goicoechea et al., 2006). Therefore, we conclude that these species originate in a physically different region to that responsible for the CO emission. It is also possible that the inferred H_2O and OH abundance are underestimated due to the enhanced contributions from shocked components being diluted in the large LWS beam. This is because H_2O and OH emission lines were modelled by a different technique by the use of only a radiative transfer model, in which only one abundance for both species needed to be assumed.

We found the technique used here to be very efficient for understanding the chemistry and ideal for modelling high spectral and spatial resolution data. Future heterodyne instruments, such as HIFI on the ESA Herschel Space Observatory, with their much higher spatial and spectral resolution, will be better able to distinguish the different components in the complex region of Orion-KL and, together with modelling techniques such as those developed here, should be capable of providing new insights into cloud chemical evolution during the process of massive star formation.

ACKNOWLEDGEMENTS

This work was carried out on the Miracle Supercomputer, at the HiPerSPACE Computing Centre, UCL, which was funded by the U.K. Particle Physics and Astronomy Research Council. The *ISO* Spectral Analysis Package (ISAP) is a joint development by the LWS and SWS Instrument Teams and Data Centres. Contributing institutes are CESR, IAS, IPAC, MPE, RAL and SRON. LIA is a joint development of the *ISO*-LWS Instrument Team at Rutherford Appleton Laboratories (RAL, UK- the PI institute) and the Infrared Processing and Analysis Center (IPAC/Caltech, USA).
